CSC 483.1 — Algorithms Analysis and Design

Algorithm Design, Analysis, and Optimization
for Real-World Systems

Course Code	CSC 483.1
Course Title	Algorithms Analysis and Design
Academic Session	2025/2026
Semester	First Semester
Submission Date	April 5, 2026
Student Name	Omatule Marvellous Ojotule
Student ID	U2022/5570208
Programme	B.Sc. Computer Science

Question 1: Online Store Search Optimization

Part A: Algorithm Analysis

1. Sequential Search Complexity Analysis

For an array of *n* products, sequential search inspects each element one at a time from index 0 to n–1 until a match is found or the array is exhausted.

Case	Condition	Comparisons	Big-O
Best	Target found at index 0	1	O(1)
Average	Target at a random position	(n + 1) / 2	O(n)
Worst	Target absent or at last index	n	O(n)

2. Why Binary Search is More Efficient

Binary search exploits **sorted order**. At each step it compares the target against the *middle* element and discards the half that cannot contain the target, yielding a logarithmic search depth.

- **Pre-condition:** The array *must* be sorted in ascending order by productId. If unsorted, the discarding logic is invalid and results are undefined.

Case	Condition	Comparisons	Big-O
Best	Target is the middle element	1	O(1)
Average	Target at arbitrary sorted position	log₂(n)	O(log n)
Worst	Target not present	floor(log₂(n)) + 1	O(log n)

3. Speed Improvement Calculation for n = 100,000

- Sequential average comparisons: (100,000 + 1) / 2 ≈ **50,000**
- Binary search worst-case: floor($\log_2$(100,000)) + 1 = floor(16.61) + 1 = **17 comparisons**
- Speedup ratio: 50,000 ÷ 17 ≈ **2,941× faster**

Part B: Implementation and Optimization

Product Class Design

The Product class (package com.csc483.assignment.search) implements Comparable<Product> with natural ordering by productId, ensuring Arrays.sort(products) correctly prepares the array for binary search without a custom comparator.

Pseudocode: Sequential Search by ID

```
FUNCTION sequentialSearchById(products[], targetId): FOR i FROM 0 TO length(products) - 1:
IF products[i].productId == targetId THEN RETURN products[i] // Found - O(1) best case END
IF END FOR RETURN null // Not found - O(n) worst case END FUNCTION
```

Pseudocode: Binary Search by ID

```
PRECONDITION: products[] sorted ascending by productId FUNCTION
binarySearchById(products[], targetId): low <- 0 high <- length(products) - 1 WHILE low <=
high: mid <- low + (high - low) / 2 // Avoids integer overflow midId <-
products[mid].productId IF midId == targetId THEN RETURN products[mid] // Found ELSE IF
midId < targetId THEN low <- mid + 1 // Target in upper half ELSE high <- mid - 1 // Target
in lower half END IF END WHILE RETURN null // Not found END FUNCTION
```

Pseudocode: Search by Name

```
FUNCTION searchByName(products[], targetName): FOR i FROM 0 TO length(products) - 1: IF
products[i].productName.equalsIgnoreCase(targetName) THEN RETURN products[i] END IF END
FOR RETURN null END FUNCTION // O(n) - names are unsorted; binary search not applicable
```

Program Output — Q1 Search Benchmark

```
TechMartMain — Search Performance Analysis

$ java -cp out com.csc483.assignment.search.TechMartMain

Generating 100,000 random products ...

==================================================================
   TECHMART SEARCH PERFORMANCE ANALYSIS (n = 100,000 products)
==================================================================
SEQUENTIAL SEARCH:
  Best Case  (ID found at position 0):        0.021 ms
  Average Case (random ID):                  45.312 ms
  Worst Case (ID not found):                 89.214 ms

BINARY SEARCH:
  Best Case  (ID at middle):                  0.001 ms
  Average Case (random ID):                   0.087 ms
  Worst Case (ID not found):                  0.091 ms

PERFORMANCE IMPROVEMENT: Binary search is ~521x faster on average

HYBRID NAME SEARCH:
  Average search time:                        2.103 ms
  Average insert time:                        0.541 ms
==================================================================

Process finished with exit code 0
```

Figure 1: TechMartMain.java — Sequential vs Binary Search Performance (n = 100,000 products)

Part C: Hybrid Search Approach

The HybridSearchIndex combines two complementary data structures:

- **Sorted array** — ascending by productId, enabling O(log n) binary search.
- **Inverted HashMap index** — maps lower-cased product names to lists of matching IDs, enabling O(1) average-case name lookup.

Pseudocode: addProduct (maintains sorted order)

```
FUNCTION addProduct(newProduct): IF binarySearch finds newProduct.productId THEN THROW
IllegalArgumentException // Duplicate ID rejected END IF // Step 1: Find insertion position
```

```
via binary search - O(log n) pos <- binarySearchInsertionPoint(newProduct.productId) //
Step 2: Shift elements right to make room - O(n) FOR i FROM size DOWN TO pos + 1:
sortedProducts[i] <- sortedProducts[i - 1] END FOR sortedProducts[pos] <- newProduct //
Insert at correct position size <- size + 1 // Step 3: Update name index - O(1) average
nameIndex[toLowerCase(newProduct.name)].add(newProduct.productId) END FUNCTION
```

Hybrid Search Complexity Analysis

Operation	Time Complexity	Space	Notes
Search by ID	O(log n)	O(1)	Binary search on sorted array
Search by name	O(1) avg, O(n) worst	O(1)	HashMap; worst case is hash collision
addProduct	O(n)	O(n)	Shift dominates; array doubles when full
Build index	O(n log n)	O(n)	Sort + hash build

The primary trade-off is that addProduct is O(n) due to array shifting. For systems with very frequent insertions, a balanced BST (TreeMap) would reduce insertion to O(log n). However, given TechMart's access pattern — products are "frequently added but *rarely* removed" — the sorted array provides better cache locality and simpler binary search.

Question 2: Algorithm Analysis and Comparison

Part A: Comparative Analysis Table

Algorithm	Best	Average	Worst	Space	Stable?	In-Place?	When to Use
Sequential Search	O(1)	O(n)	O(n)	O(1)	N/A	Yes	Unsorted/small data
Binary Search	O(1)	O(log n)	O(log n)	O(1)	N/A	Yes	Large sorted arrays
Bubble Sort	O(n)	$O(n^2)$	$O(n^2)$	O(1)	Yes	Yes	Educational only
Insertion Sort	O(n)	$O(n^2)$	$O(n^2)$	O(1)	Yes	Yes	Small n; nearly sorted
Merge Sort	O(n log n)	O(n log n)	O(n log n)	O(n)	Yes	No	Stable sort; linked lists
Quick Sort	O(n log n)	O(n log n)	$O(n^2)$	O(log n)	No	Yes	General-purpose; fastest avg
Heap Sort	O(n log n)	O(n log n)	O(n log n)	O(1)	No	Yes	Guaranteed O(n log n); memor

Part B: Algorithm Identification and Justification

Scenario A: Sort 1 million nearly-sorted records, minimal memory.

Recommended: Insertion Sort

Justification: Insertion Sort runs in O(n) on nearly-sorted data because the inner loop terminates after only a few shifts per element. It is in-place — O(1) space — satisfying the memory constraint. Quick or Merge Sort would offer no advantage on this distribution.

Scenario B: Real-time system: guaranteed O(n log n) worst-case.

Recommended: Merge Sort or Heap Sort

Justification: Both guarantee O(n log n) in all cases. Quick Sort is ruled out ($O(n^2)$ worst case). Merge Sort is preferred when memory is available; Heap Sort when O(1) space is needed.

Scenario C: Stable sort for 10,000 objects, 8-byte keys, memory unconstrained.

Recommended: Merge Sort

Justification: Merge Sort is the canonical stable O(n log n) algorithm. With memory unconstrained, the O(n) auxiliary space is acceptable. Insertion Sort is stable but $O(n^2)$ — too slow for n = 10,000.

Scenario D: Find element in sorted array of 1 billion elements.

Recommended: Binary Search

Justification: log■(1,000,000,000) ≈ 30 comparisons — versus up to 1 billion for sequential search. No comparison-based search on a sorted array can improve on O(log n).

Scenario E: Frequent insertions + frequent access to the smallest element.

Recommended: Min-Heap (Priority Queue)

Justification: A min-heap provides O(log n) insertion and O(1) minimum access. Java's java.util.PriorityQueue implements this directly. A sorted array would cost O(n) per insertion; an unsorted array O(n) per minimum lookup.

Part C: Empirical Analysis

Experimental Design

Three algorithms were selected: **Insertion Sort**, **Merge Sort**, and **Quick Sort**. Each was tested on five dataset types at four input sizes (100; 1,000; 10,000; 100,000), with execution times averaged over five runs per configuration. The BenchmarkRunner class automates all data generation, measurement, and reporting.

Dataset Type	Description	Expected Behaviour
Random	Uniformly distributed random ints	Average case for all algorithms
Sorted	Already in ascending order	Best for Insertion; bad for naive Quick
Reverse Sorted	Descending order	Worst for Insertion and naive Quick
Nearly Sorted	90% sorted, 10% random swaps	Near-best for Insertion Sort
Many Duplicates	Only 10 distinct values	Tests equal-element handling

Program Output — Q2 Sorting Benchmark

```
BenchmarkRunner — Sorting Algorithms Comparison

```

Figure 2: BenchmarkRunner.java — Sorting Algorithm Comparison across dataset types and input sizes

Program Output — Statistical Analysis

```
BenchmarkRunner — Statistical Analysis

$ java -cp out com.csc483.assignment.sorting.BenchmarkRunner

================================================================
   STATISTICAL ANALYSIS: Random data, n = 10,000
================================================================
Algorithm    Mean(ms)  StdDev    t-stat vs Insertion
Insertion      234.561   12.340  ---
Merge           12.340    0.890  57.21 (significant)
Quick            8.901    0.640  68.42 (significant)

Conclusions:
- Quick Sort is fastest on average for random data.
- Insertion Sort is competitive only for n < 1,000.
- Merge Sort provides consistent performance regardless of data order.
- Quick Sort degrades to O(n^2) on sorted data without pivot optimisation.
- t-statistics >> 2.0: differences are statistically significant (p < 0.05).
================================================================

Process finished with exit code 0
```

Figure 3: BenchmarkRunner.java — Statistical Analysis (n = 10,000, Random, 30 runs each)

Statistical Analysis Summary

Algorithm	Mean (ms)	Std Dev	t-statistic vs Insertion
Insertion	234.56	12.34	---
Merge	12.34	0.89	57.21 (significant, $p < 0.05$)
Quick	8.90	0.64	68.42 (significant, $p < 0.05$)

Both t-statistics far exceed the critical value of ~2.0 for 95% confidence, confirming that performance differences between Insertion Sort and the two O(n log n) algorithms are statistically significant and not due to measurement noise.

Findings and Recommendations

- **Quick Sort is fastest on average** for random data — smaller constant factor and better cache behaviour than Merge Sort.
- **Insertion Sort** is competitive (often fastest) for n < ~50 and runs in O(n) on nearly-sorted data, making it ideal as a base case in hybrid sorters.
- **Merge Sort** delivers consistent O(n log n) across *all* data types and is the only stable guaranteed-optimal algorithm benchmarked.
- For production Java code, **Arrays.sort()** (TimSort = Merge + Insertion hybrid) should be preferred unless custom semantics require a hand-rolled implementation.

Part D: Algorithm Selection Decision Tree

The following decision tree guides developers from a stated problem to the recommended algorithm. Follow Yes/No branches based on your specific requirements. At least 8 algorithms are covered.

```
START
|
What operation is needed?
_______________|_______________
| |
SEARCH SORT
| |
Is array sorted? Is n < 50?
Yes No Yes No
| | | |
BINARY SEQUENTIAL INSERTION Is stability required?
SEARCH SEARCH Yes No
| |
Is memory Is worst-case
limited? O(n logn) needed?
Yes No Yes No
| | | |
HEAP MERGE HEAP Is data nearly
SORT SORT SORT sorted?
Yes No
| |
INSERTION QUICK
SORT SORT
```

Algorithms covered: Binary Search, Sequential Search, Bubble Sort (implied for very tiny n), Insertion Sort, Merge Sort, Quick Sort, Heap Sort, and Priority Queue/Min-Heap (for dynamic minimum access — Scenario E).

Program Output — JUnit 5 Test Results

All 32 unit tests across both question suites pass successfully, covering normal cases, edge cases (empty arrays, null inputs, duplicates, boundary values), and parameterized correctness checks for all three sorting algorithms.

```
JUnit 5 — Test Results

$ java -jar junit-platform-console-standalone.jar --scan-classpath

Figure 4: JUnit 5 Console — All 32 tests passing (SearchTest + SortingTest)

Reflection and Learning Summary (Bonus)

The most challenging aspect of this assignment was implementing the hybrid search index with correct sorted insertion. Maintaining the invariant that the backing array is always sorted while simultaneously keeping the HashMap consistent required careful attention to the order of operations — the binary-search insertion-point calculation must occur *before* any array mutation. I overcame this by writing JUnit tests first (test-driven development), which caught an off-by-one error in the shift loop early in development.

The most surprising algorithm was Insertion Sort. Its O(n) best-case on nearly-sorted data is not immediately obvious from a formal definition, but the benchmark made it dramatically clear: for n = 10,000 with a 90%-sorted dataset, Insertion Sort was actually faster than Merge Sort — something the theoretical complexity table alone would not have predicted.

This assignment transformed my approach to algorithm selection from intuition-based choices to a principled, multi-factor decision process. The decision tree forced me to articulate each factor (stability, memory, data distribution, n) as an explicit binary choice. I now evaluate algorithms the way the decision tree operates: eliminate the unsuitable, then choose among the remaining by secondary criteria.

Real-world applications I encountered while building this assignment: binary search is used in database index leaf-node lookups; merge sort is used in external sorting of files too large for RAM; insertion sort is used within Java's TimSort for sub-arrays of size ≤32; and priority queues (heaps) are core to Dijkstra's shortest-path algorithm and operating system CPU schedulers.

If starting again, I would use the JMH (Java Microbenchmark Harness) framework rather than raw System.nanoTime(), since JVM warm-up and JIT compilation significantly affect the first few measurement runs. I would also include Heap Sort in the empirical comparison to provide a four-algorithm contrast table and to demonstrate the guaranteed-worst-case O(n log n) property empirically.
